The North Saskatchewan Watershed Alliance (NSWA) is a non-profit society whose purpose is to protect and improve water quality and ecosystem functioning in the North Saskatchewan River watershed in Alberta. The organization is guided by a Board of Directors composed of member organizations from within the watershed. It is the designated Watershed Planning and Advisory Council (WPAC) for the North Saskatchewan River under the Government of Alberta's *Water for Life Strategy*.

This report was prepared by Ms. Jennifer Regier, B.Sc. and Mr. David O. Trew, P. Biol. of the North Saskatchewan Watershed Alliance.

Executive Summary

This report provides a descriptive compilation of stream nutrient data collected in Alberta between 1977 and 2013. The purpose was to consolidate information from many diverse sources into one document and to provide a useful reference point for future studies of lake and watershed management in this province.

Stream nutrient data from eleven watershed studies are presented for ten lake watersheds. These include streams draining into Baptiste Lake, Wabamun Lake, Lac La Nonne, Pine Lake, Lesser Slave Lake, Lac Ste. Anne, Lake Isle, Gull Lake, Lac la Biche and Pigeon Lake. Most of these studies were conducted by Alberta Environment (AENV); some were conducted by faculty and graduate students at the University of Alberta.

This document also includes data from detailed studies conducted on a large selection of streams draining agricultural watersheds with varying degrees of agricultural intensity and runoff. These longer-term studies were conducted jointly by Alberta Environment and Alberta Agriculture & Rural Development. These included the *Canada-Alberta Environmentally Sustainable Agriculture* (CAESA 1998) and *Alberta Environmentally Sustainable Agriculture* (AESAs 2008) projects. A smaller stream study from the Swan Hills is also included (Munn and Prepas 1986).

Data were compiled for 108 streams; several streams were sampled for more than one year providing a total of 190 years of stream data. The compiled data are presented in graphical and tabular formats as Annual Flow-Weighted Mean Concentrations (AFWMCs) and Annual Export Coefficients (AECs). Twenty nutrient fractions and ratios are presented.

Acknowledgements

The authors thank Ms. Marilou Montemayor (NSWA), Mr. Gord Thompson (NSWA), Dr. Les Gammie (NSWA) and Ms. Alyssa Tuininga (AESRD) for reviewing this document. Ms. Candace Vanin (Agriculture Canada) and Ms. Mary Ellen Shain (NSWA) assisted with mapping. Ms. Melissa Logan (NSWA) formatted the final document.

1.0 Introduction

Many Alberta lakes display advanced symptoms of eutrophication as a result of high nutrient concentrations. Over the years a number of watershed-scale studies have been conducted on Alberta lakes to develop nutrient budgets and to measure phosphorus and nitrogen loadings via tributary streams. The study streams drained both forested and agricultural watersheds. These variations in land cover are thought to have a major influence on runoff water quality.

Phosphorus is considered to be the most common limiting chemical factor for algal growth in freshwater lakes (Trimbee and Prepas 1987; Schindler et al. 2008). The nitrogen content of freshwater lakes can also be an important factor and may influence the patterns of algal succession that occur during the open-water growing season (Prepas and Trimbee 1988). Other factors such as salinity, turbidity and physical mixing patterns are important determinants of the quantity and types of algae that develop (Bierhuizen and Prepas 1985). Algal blooms are a major feature of summer water quality in Alberta lakes, affecting water transparency and aesthetics and influencing other lake features such as oxygen concentrations and cyanotoxicity. The control of excessive summer algal blooms is therefore an important goal of lake management in this province.

The development of phosphorus budgets has become commonplace in the lake research and management literature, and they are used as diagnostic tools to quantify pollution sources and evaluate long-term management options for lakes (Dillon and Rigler 1974; Rast and Lee 1978; Teichreb 2014). The development of phosphorus budgets and models has been an ongoing field of limnological research since the first watershed/lake nutrient relationships were developed in the 1960s (Vollenweider 1968). Stream surveys are one component of phosphorus budgets.

Although many studies have shown increases in stream phosphorus and nitrogen in agricultural areas, it is important to acknowledge natural variations. Soils are particularly relevant since agricultural lands are often found in nutrient rich regions. This makes it difficult to determine the proportions of anthropogenic and natural influences on phosphorus in streams, especially when there are few reference sites available for comparison. Additional geologic and hydrologic controls can affect phosphorus levels and should also be considered when assessing stream nutrient data (Dillon and Kirchner 1975; Gburek and Sharpley 1998; Donahue 2013).

This report provides a basic compilation of the nutrient data collected between 1977 and 2013 during these various Alberta stream studies. The purpose is to consolidate information into one document and provide an additional reference point for future studies of lake and watershed management. Data from a total of 108 individual streams are presented in graphical and tabular formats as Annual Flow-Weighted Mean Concentrations (AFWMCs) and Annual Export Coefficients (AECs). Twenty nutrient fractions and ratios are presented. Interpretation of the compiled data is limited in scope; the authors recommend further evaluation.

2.0 Background Information

2.1 Eutrophication of Alberta Lakes

Eutrophication is a process in which lakes may become increasingly more productive - a process that occurs naturally, but can be accelerated by human activities. It is driven by enhanced nutrient inputs, particularly phosphorus. The eutrophication process is also influenced by the physical and chemical characteristics of the individual lake (e.g., depth, flushing, salinity) as well as the size of the watershed, land cover, local climate, etc.

The trophic state of a lake refers to its level of biological productivity and is usually defined in terms of its phosphorus and chlorophyll *a* concentrations. Lakes are categorized along a trophic spectrum: oligotrophic (low productivity), mesotrophic (moderate productivity), eutrophic (high productivity) and hypertrophic (very high productivity).

Both internal and external sources of phosphorus contribute to lake eutrophication. In shallow Alberta lakes, phosphorus concentrations increase rapidly in mid to late summer as phosphorus is released from lake bottom sediments in a process referred to as “internal loading” (Figure 1). The response of the phytoplankton community is equally rapid and algal blooms quickly develop during these ideal conditions of fertility, warm weather and ample sunlight. Phosphorus and other nutrients also enter lakes through a variety of external loading pathways including tributaries, groundwater, atmospheric inputs and shoreline sources (Figure 2).

Many Alberta lakes are naturally eutrophic due to the presence of fertile watershed soils (Mitchell and Trew 1992). However, natural lake productivity is being amplified by human disturbance. Paleolimnological evidence suggests that changes occurred during the 1950s to 1970s due to the combined effects of converted land cover, agricultural intensification, increased cottage development and related hydrologic impacts (AESRD 2007).

2.2 Hydrologic Influences on Nutrient Loading

Runoff in streams on the Alberta plains is largely driven by snowmelt. An example of a plains stream hydrograph (Strawberry Creek) is presented in Figure 3. Discharges are typically highest during spring runoff and gradually decrease, with the exception of a few summer storm events that can briefly raise flow rates. Snowmelt was observed to contribute over 90% of annual runoff in eight Alberta watersheds in a study conducted by Little et al. (2007). The shape of the hydrograph greatly influences the timing of nutrient loading. The high volume of water accompanied by the release of nutrients from frozen snow, soils and plant residue generally results in the greatest nutrient flux occurring during the spring snowmelt period. Snowmelt runoff also contributes to overall water quality issues related to total organic carbon (TOC), colour, bacteria, protozoans, taste and odour. An example of the seasonal pattern in phosphorus concentrations for a small forested stream at Baptiste Lake is presented in Figure 4.

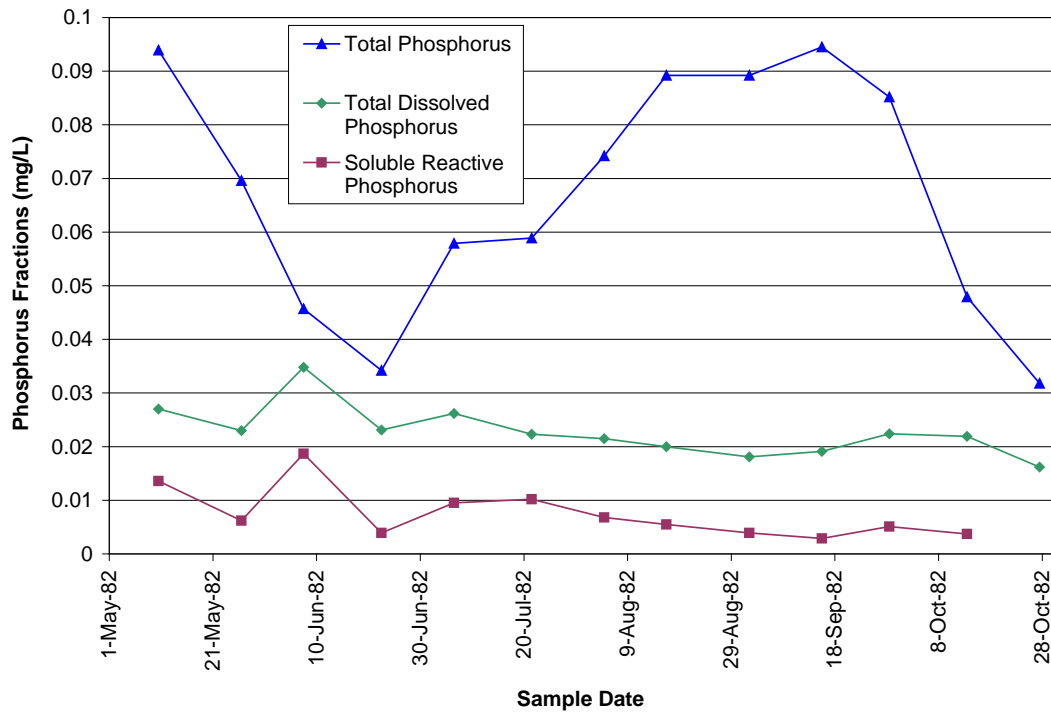

Figure 1. Seasonal fluctuations in phosphorus fractions in Tucker Lake, 1982 (Source: Chow-Fraser and Trew 1990)

Figure 2. Typical phosphorus sources to lakes (Source: AESRD 2014)

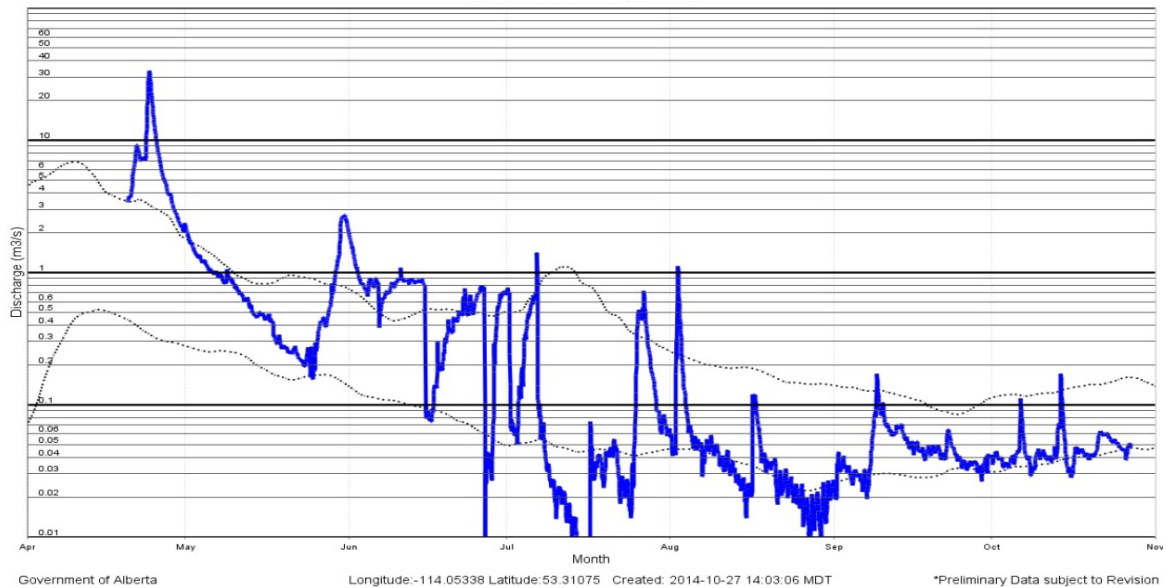

Figure 3. Hydrograph for Strawberry Creek near the Mouth (Station 05DF004) for April to November; current year (2014) shown in blue; normal range (quartiles) shown in grey (Source: AESRD 2014)

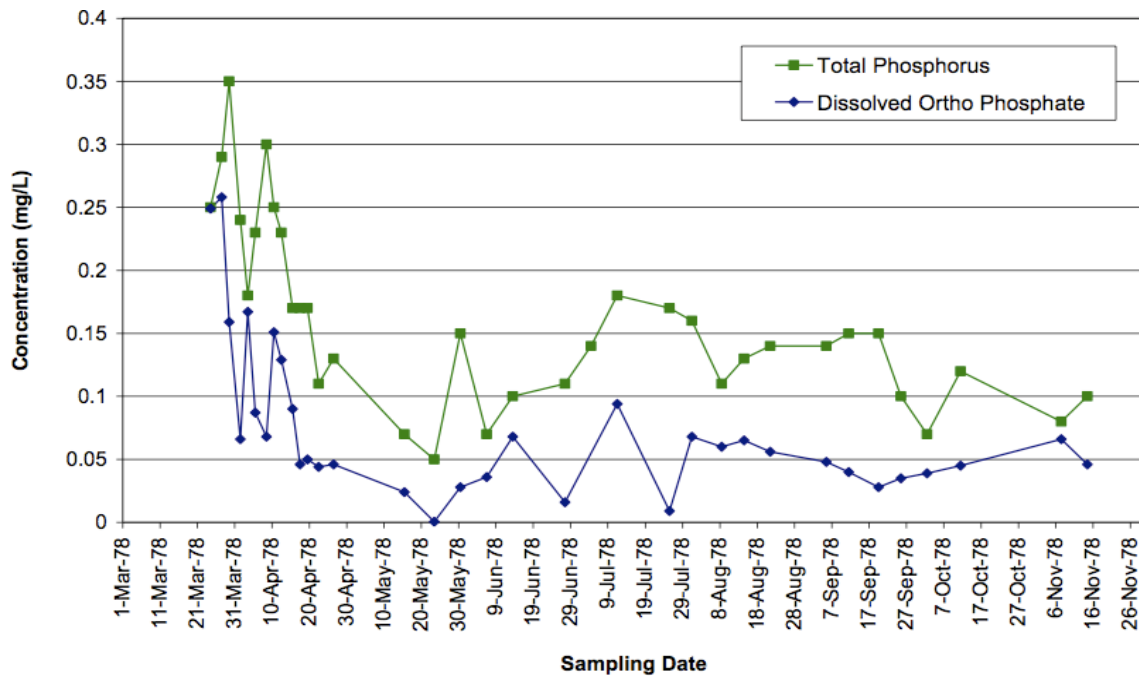

Figure 4. Seasonal fluctuations in total phosphorus concentrations in Stream E, Baptiste Lake (Source: Trew et al. 1987)

Thus, stream nutrients are often concentrated in the earlier part of the open-water season. Streams that only flow during this time often have a much higher concentrations and loads relative to their total volume of flow. Not all streams follow this truncated ephemeral pattern, but it is important to consider this attribute when comparing AFWMCs within and among watersheds. Flow effects should also be understood when evaluating AECs, which can exhibit great variations from year to year for individual streams, depending on inter-annual runoff and loading variations. AFWMCs are useful in describing and modeling nutrient load patterns because they minimize the variability within and among stream types over time (Anderson 2006).

2.3 Natural Regions and Land Cover Influences

Stream loading patterns are influenced by the characteristics of the soil and the vegetation that are encountered and transported during runoff events. Eco-regions are the natural indicators of base soil and vegetation characteristics. Strong relationships between soil phosphorus levels and concentrations of phosphorus in runoff have been documented in southern and central Alberta (Little 2007).

Soil nutrients are naturally lower in the mountain headwater regions and higher in Parkland and Boreal Forest eco-regions (AESRD 2014). Land cover changes within an eco-region cause variations in the quantity and quality of runoff from base conditions. Nutrient runoff data are therefore best aggregated and compared for streams within similar eco-regions (Anderson 2006).

Not all land cover types have the same effect on nutrient loading. A number of agricultural land cover types have been loosely ranked according to their nutrient contribution. A summary of total phosphorus (TP) export coefficients for southern Alberta agricultural areas concluded that export coefficients from feedlots were generally much higher than other types, followed by corn/soybeans, row, non-row, grazed, fallow, dairy, and alfalfa crops (Jeje 2003). These ranges are not always consistent due to variations in soil management, runoff and crops planted. While clearing of vegetation generally results in greater sediment and particulate nutrient flux in runoff, the presence of live groundcover over winter can increase the contribution of dissolved phosphorus and nitrogen fractions (Elliott 2013). The numerous freeze-thaw cycles common to prairie spring melts are thought to increase cell rupturing and release water soluble phosphorus. This process is more dependent on moisture content than nutrient content and may produce high runoff concentrations when green plants are actively growing at first frost, including recently seeded clover, winter wheat, and alfalfa (White 1973; Robertson 2007; Elliott 2013).

In light of these various findings, beneficial management practices (BMPs) are being promoted throughout Alberta (CAESA 1998; Paterson et al. 2006; Olson et al. 2011). These include applying nutrients only as needed, keeping livestock away from streams and lakes, managing

manure storage and spreading to avoid groundwater contamination, and preventing soil nutrients from getting to the water by reducing tillage and increasing vegetation cover in areas susceptible to erosion. More research and monitoring of BMPs are required to further understand their effectiveness and implications in different regions of Alberta.

2.4 Water Quality Guidelines

Guidelines for water quality are science-based recommendations that provide “the best estimate of no-effect thresholds or safe levels for the particular use and substance in question” (AESRD 2014). Concentrations of 0.05 mg/L for Total Phosphorus and 1.0 mg/L for Total Nitrogen were used previously as the Alberta Surface Water Quality Guidelines (ASWQG) for the Protection of Aquatic Wildlife (PAL) (AESRD 2014). Over the past few years, a case has been made for site-specific guidelines. Unlike PAL guidelines, these attempt to account for biogeochemical differences unique to individual ecoregions and water bodies, requiring extensive understanding of the local limnology, hydrogeology, point and non-point sources (Anderson 2006). Interim regional guidelines can be put in place while site-specific ones are being developed. For the present, AESRD has replaced the former PAL guidelines with narrative guidelines (Table 1).

Other guidelines for phosphorus were suggested via the Soil Phosphorus Limits Project developed by Alberta Agriculture and Rural Development (Paterson et al. 2006). The project was based on the conclusion of Little et al. (2007) that soil test phosphorus (STP) relates directly to runoff concentrations and was concerned with the implications of limits for both agriculture and water quality. Using hypothetical guidelines of 1.0 mg/L (Alberta Environment’s limit for point source discharge from waste-water treatment plants) and 0.5 mg/L, the level of STP required to meet these guidelines was calculated. The project determined that soil test phosphorus levels should be kept below 60 ppm over very large areas of agricultural land. Although this level is also considered to be the agricultural threshold over which plant response to phosphorus increase is minimal, it was concluded that setting such limits was not reasonable from a management and policy perspective.

The greatest perceived hurdle for implementing these limits was transportation costs to properly spread manure beyond concentrated livestock regions. It was also suggested by Patterson et al. (2006) that the high runoff concentrations were not significantly impacting the main stem of major river systems. Beneficial Management Practices (BMPs) were strongly encouraged with a focus on riparian areas and tributaries.

Table 1. Surface water quality guidelines for nutrients
(Source: AESRD 2014)

Water Body Type	Guideline
Lakes	No increase in nitrogen (total) or phosphorus over existing conditions. Where nitrogen and/or phosphorus have increased due to human activity, develop lake-specific nutrient objectives and management plans where warranted.
Major River (Interim*)	For major rivers, nitrogen (total) and phosphorus concentrations should be maintained so as to prevent detrimental changes to algal and aquatic plant communities, aquatic biodiversity, oxygen levels and recreational quality. Where priorities warrant, develop site-specific nutrient objectives and management plans.
Other Water Bodies	For surface waters not covered by specific guidelines, nitrogen (total) and phosphorus concentrations should be maintained so as to prevent detrimental changes to algal and aquatic plant communities, aquatic biodiversity, oxygen levels, and recreational quality. Where priorities warrant, develop site-specific nutrient objectives and management plans.

**Work to develop science-based numeric guidelines for major Alberta rivers is ongoing*

3.0 Study Area

Most streams included in this report are located in central Alberta; however the north-south extent ranges from Hines Creek (approximately 130 km north of Grande Prairie, AB) to Prairie Blood Coulee (approximately 20 km southwest of Lethbridge, AB). The region is generally characterized by rich soils and high agricultural activity in the form of various livestock and grain operations. A number of undisturbed forested streams, located in the Boreal Ecoregion, are also included in this compilation. Stream locations are presented on the Alberta Ecoregion map (Figure 5).

Figure 5. Alberta Natural Regions map with stream locations.

4.0 Compilation Methods

4.1 Data Collection

The individual studies included in this compilation are listed in Table 2 along with their year(s) of study, number of streams sampled and numbers of samples (sampling days). Note that some streams were resampled during later studies. Nutrient fractions collected are listed in Table 3. This is not a comprehensive list of all stream nutrient data for Alberta, but rather a compilation of studies known to report annual loads and/or concentrations. Data were obtained directly from databases, grey literature and scientific publications. Most studies were sourced from Alberta Environment and Alberta Agriculture & Rural Development.

4.2 Data Analysis

Calculated values

Annual Flow Weighted Mean Concentrations (AFWMCs) and Annual Export Coefficients (AECs) are the metrics presented in this report. In cases where the desired metric was not reported directly these values were derived from data presented in the original studies. AFWMCs (mg/L) were calculated by dividing the reported annual load by the reported annual discharge. AECs (kg/ha/yr) were determined by dividing the reported annual load by the stream basin area. A summary of the metrics compiled is presented in Table 4.

Box plots

Box plots were created to illustrate the range of AFWMCs and AECs compiled for each nutrient fraction. Plots for both metrics were also compiled for TP and TN by study and by ecoregion. Each AFWMC and AEC value is from a single stream year and “n” is indicated for each category. The error bars indicate the maximum and minimum values. The box shows the values ranging from the first to the third quartile (the middle 50% of the data). The line dividing the box horizontally indicates the median. Thus, each section represents one quarter of the data for each category.

Histograms

Summary histograms were created to show the provincial range of AFWMCs and AECs for TP and TN according to land cover type. The median of AFWMC and AEC values was calculated for each stream and plotted as the single data point for that stream. For many streams, no calculation was required as there was only one metric presented (either from a single year or a pre-calculated median, as in the AESA study).

Table 2. Summary of data sources compiled for this report listed chronologically by study type (lake watershed or stream). Each time a new stream was compiled, it was added to the “Stream Tally”. Some streams were studied more than once so the number of “Streams per Study” is also listed. “Stream Years” consist of multiple streams sampled in the same year and/or multiple years of the same stream. Multi-year averages presented in the original studies were treated as single stream years where indicated (^o). “Sample Days” are as reported in the original studies or estimated (*) using raw data or sampling descriptions.

Study	Year(s) sampled	Stream Tally	Streams per Study	Stream Years	No. Sample Days

Table 3. Nutrient fractions compiled from studies listed in Table 2.

Phosphorus Fractions		Nitrogen Fractions	
TP	Total phosphorus	TN	Total nitrogen
TDP	Total dissolved phosphorus	TDN	Total dissolved nitrogen
PP	Particulate phosphorus	PN	Particulate nitrogen
FPP	Fine particulate phosphorus	TON	Total organic nitrogen
CPP	Course particulate phosphorus	TKN	Total Kjehlidahl nitrogen
SRP	Ortho-phosphate	NO ₂ /NO ₃	Nitrite & nitrate
BAP	Biologically available phosphorus	NO ₂	Nitrite
DRP	Dissolved reactive phosphorus	NO ₃	Nitrate
TDP:TP	Ratio dissolved to total phosphorus	NH ₃	Ammonia
		NH ₄	Ammonium
		DIN:TN	Ratio inorganic to total nitrogen

Many studies designated streams as draining a particular land cover. The criteria for assigning these land cover types varied from study to study. Information on land cover types and percent coverage during the study year(s) was also varied, making it difficult to create universal categories without manipulating the data beyond the intent of this compilation. The original designations were kept and are explained for each study in Table 5. Some streams not originally designated as a particular land cover type were later assigned designations during the CAESA study. Undesignated streams were given a broad designation (Forested or Agriculture) for the Natural Region boxplots (Figures 10, 11, 14 and 15). These are indicated in brackets.

Hydrology & Climate

A selection of long-term precipitation data was compiled to illustrate the climate context of the various study years. Precipitation values were collected from Environment Canada's Historic Weather website for the lake watershed study locations and Sakwatamau River. Annual precipitation for the study year and the 1981-2010 Climate Normals were collected from the nearest station possible.

Flow data were obtained from the studies themselves. The majority of flows reported were presented as annual discharges for individual streams and are included in the results section for information. Flows from the other studies may be found in the original documents in various other formats, such as instantaneous flows and graphs, but not always as annual flow volumes.

Table 4. Summary of nutrient metrics presented in this report as Annual Flow-Weighted Mean Concentrations (AFWMC) and Annual Export Coefficients (AEC). Studies area listed chronologically by type (lake watershed or stream). Most metrics were directly presented in the original study (√). Others were calculated using reported annual loads, discharges and stream basin areas where available (●).

Table 5. Land cover designation and criteria as specified in original stream reports or the CAESA summary. Broad designations (Forested/Agriculture) for undesignated streams are in brackets.

Study	Criteria	Designation
Lake Watershed Studies		
Baptiste Lake (Trew et al. 1987)	>85% cultivated land >85% forested land	Agriculture Forested
Wabamun Lake (Mitchell 1985)	<75% forested >85% forested	Mixed Agriculture Forested
Majeau Creek Lac La Nonne (Mitchell & Hamilton 1982)	cattle dominated averaging 15 animal units per square kilometer where 1 animal unit = 1 cow = 180 poultry	Agriculture (assigned by CAESA)
Pine Lake (Sosiak & Trew 1996)	50% cleared land with intensive shoreline development and livestock access to streams 1, 3, 4, and 6	Agriculture (assigned by CAESA)
Lesser Slave Lake (Noton 1998)		Undesignated (Forested) (majority forested with some agricultural activity in each stream watershed; important recreational lake)
Baptiste Lake (Cooke & Prepas 1998)	>85% cultivated land >85% forested land	Agriculture Forested
Lac Ste. Anne & Lake Isle (Mitchell 1999)		Undesignated (Agriculture) (important recreational lakes with strong agricultural presence – no land cover percentages available)
Gull Lake (Mitchell & LeClair 2003)		Undesignated (Agriculture) (important recreational lake with strong agricultural presence – no land cover percentages available)
Lac La Biche (Neufeld 2005)	~ 70% forest ~ 40% agriculture	Reference (hence forth 'Forested') Agriculture (for details see Table A2-1)
Wabamun Lake (Emmerton 2008)		Undesignated (Forested/Agriculture) (for details see Table A2-2)
Pigeon Lake (Teichreb 2014)		Undesignated (Agriculture) (for details see Table A2-3)
Stream Studies		
Sakwatamau Two Creek (Munn & Prepas 1986)	mixed boreal forest	Forested (assigned by CAESA)
CAESA (Anderson et al. 1998)	Agricultural intensity rankings based on fertilizer expense, chemical expense, and animal unit density: <i>0 to 25th percentile</i> <i>25th to 75th percentile</i> <i>75th to 100th percentile</i>	Low Intensity Agriculture Moderate Intensity Agriculture High Intensity Agriculture
AESA (Lorenz et al. 2008)	Agricultural intensity rankings based on fertilizer expense, chemical expense, and manure production: <i>0 to 40th percentile</i> <i>40th to 75th percentile</i> <i>75th to 100th percentile</i>	Low Intensity Agriculture Moderate Intensity Agriculture High Intensity Agriculture

5.0 Results

5.1 Calculated Values

See Appendix 3. Values in bold font were calculated by NSWA. The remaining values are as reported in the original studies.

5.2 Data Range Box Plots

All nutrient fractions

AFWMCs and AECs are presented for each nutrient fraction in Figures 6 and 7.

Total phosphorus

AFWMCs and AECs for TP are presented by study in Figures 8 and 9 and by Natural Region/Sub-Regions in Figures 10 and 11. Data for the two Baptiste and Wabamun studies are combined.

Total nitrogen

AFWMCs and AECs for TN are presented by study in Figures 12 and 13 and by Natural Regions/Sub-Regions in Figure 14 and 15. Data for the two Baptiste and Wabamun studies are combined.

5.3 Individual Stream Value Histograms

Total phosphorus

Median TP AFWMCs for individual streams are presented as histograms colour-coded by land cover type in Figure 16. Median TP AECs are presented in the same manner in Figure 17.

Total nitrogen

Median TN AFWMCs for individual streams are presented as histograms colour-coded by land cover type in Figure 18. Median TP AECs are presented in the same manner in Figure 19.

5.4 Hydrology

Annual precipitation data for selected study years compared with Climate Normals are presented in Figure 20. Available annual stream discharge data are presented in Figure 21.

6.0 Discussion

6.1 Data Range Box Plots

All nutrient parameters

A wide range of AFWMCs and AECs are evident in the various box plots presented in Figures 6 to 15. The variation is a reflection of the number of fractions reported by each study, the number of stream years available for each fraction and the variable nature of the sampling regime employed for each study.

Variations among study data also arise from the biogeochemical characteristics of the various ecoregions in Alberta, human influences and temporal factors. There are differences in soils, land cover and management practices, some of which may change over time. Weather and hydrology can vary greatly from year to year; dry years tend to generate lower flows, which often correspond to lower loadings. Many of these factors likely contribute to the variation within studies.

Total phosphorus

AFWMC and AEC values for TP display high variability in the top 25% of their data ranges. This may reflect the wider range of TP data available compared to other fractions. High values for other fractions may not have been consistently captured across the range of studies conducted.

TP variations by study

Most median AFWMC values are less than 0.5 mg/L with the exception of Gull Lake streams. These data were collected from ephemeral, short-lived streams. A similar pattern is evident in the AEC values, with the median value at Gull Lake being the highest in the data set. Sources of phosphorus were not identified in the original study, but the authors noted that the values fell within the range of streams draining high intensity agricultural lands as reported in the CAESA project (Mitchell and LeClair 2003; Anderson et al. 1998).

The streams sampled in the CAESA and AESA projects incorporated numerous ecoregions (Figure 5), agricultural intensities and flows, yet the CAESA data display a higher range of AFWMCs and AECs than the AESA data. One reason for this change could be the gradual implementation of BMPs during the more recent period of the AESA study, which may have contributed to lower nutrient losses resulting in lower loads in streams. Another possible explanation is the higher sampling frequency of the original CAESA study, in which more extreme flow events may have been captured than in the AESA sampling regime. In addition, the highest values for AECs in the CAESA study come from 1996 when Sakwatamau River was

resampled during a particularly wet year, while AFWMCs at Sakwatamau River that same year were closer to the median.

Pigeon Lake data are the newest in this compilation and record lower values than expected for a nutrient-rich agricultural area. This might be attributed to the lower precipitation in 2013 (Figure 20) or perhaps the success of improved land management practices in the watershed. In addition, samples were only taken an average of every two weeks and may have missed peak flows from spring melt or summer storms.

The remaining studies produce varying medians and ranges of AFWMCs and AECs. Values at Baptiste and Wabamun Lakes span larger ranges. This could be a result of the contrasting land cover types or perhaps the slightly larger datasets derived in this analysis by combining two studies from different decades for each lake. Smaller ranges exist at Pine Lake and Lac La Biche and even smaller ranges are apparent at Lac Ste Anne, Isle Lake, Lesser Slave Lake, and Lac La Nonne. The Pine Lake study spanned multiple years. Lac La Biche has varied land cover and geology. The remaining studies presented only one season's data or a single median from multiple years (Lesser Slave) and covered areas of more uniform land cover.

In general, studies with agricultural watersheds have higher median AFWMCs than studies with mostly forested watersheds, though it is unclear to what degree antecedent natural conditions affect these concentrations. AECs are strongly affected by flow patterns in the different study regions.

TP variations by Natural Region and Subregions

Total Phosphorus AFWMCs are plotted by Natural Regions and Natural Subregions in Figure 10. These plots provide a clear and interesting summary of the provincial nutrient patterns. Overall, the Parkland Natural Region (Central and Peace River Sub-Regions) displays the highest median and upper quartile values in stream TP concentrations. The Boreal Natural Region (Dry Mixedwood, Central Mixedwood and Lower Boreal Highlands) displays the second highest AFWMC values, followed by the Grasslands, Foothills and Alpine natural regions respectively.

The Parkland Natural Region and Dry Mixwood Natural Regions include many of the high agricultural intensity CAESA and AESA streams, as well as the Gull Lake streams previously discussed. These are naturally nutrient-rich areas, attracting much of the high intensity agriculture (AESRD 2014).

Lower TP AFWMCs in the Grasslands Ecoregion and Foothills Natural regions may be related to the lower intensity of agricultural land cover combined with natural biogeochemical conditions.

The highest median values for TP AECs are in the Boreal and Foothills Natural Regions, and may reflect the influence of higher runoff from these zones as AFWMCs are lower. The highest value for the Foothills Natural Region is for Sakwatamau River during high flows in 1996.

Total nitrogen

AFWMCs and AECs for TN, TON and TKN span a much wider range and their median values are typically an order of magnitude higher than median AFWMC values for the other nutrient fractions (Figure 6). These same nitrogen fractions also display the highest AECs (Figure 7). Ammonia and ammonium also display high variability.

TN variations by study

Ranges of AFWMCs and AECs for Total Nitrogen (Figures 12 and 13) reveal a similar pattern to TP ranges (Figures 8 and 9), with large ranges for Baptiste, Wabamun, and CAESA; a smaller range for AESA; high values at Gull Lake; and lower values at Pine, Pigeon and La Biche. The variables discussed above for TP AFWMCs and AECs are likely influential on TN data patterns as well.

TN variations by Natural Region and Subregions

Ranges of Total Nitrogen AFWMCs relative to Natural Regions (Figure 14) are again very similar to the patterns for Total Phosphorus, but with one exception. The main difference is the Dry Mixedwood maximum is slightly higher than Central Parkland. The reason for this is unclear, though many of the forested streams were found to contribute more nitrogen than phosphorus relative to other land cover types.

The box plot for TN AECs (Figure 15) is almost identical in appearance to the box plot for TP AECs (Figure 11). Higher annual flow rates (basin yields) are again perceived to have the greatest effect on the upper values in the Central Mixedwood and Lower Foothills Natural Regions.

6.2 Individual Stream Value Histograms

Figures 16 and 18 suggest that AFWMCs increase as land becomes less forested and more intensely developed, but the degree depends greatly on other variables such as ecoregion biogeochemistry, hydrology and land management. In addition, agriculture or any variation of the agricultural classification categories used here are extremely broad categories, encompassing a wide variety of practices, each with varying effects. Thus watersheds with agricultural designations create a wide range of AFWMC data.

The graphs for AECs show a similar pattern for TP, but the AECs for TN reveal a different pattern. Stream TN loadings from certain northern forested watersheds are high, and the corresponding AECs are at the higher end of the data set. This could be a reflection of the natural soil chemistry, vegetation and hydrology of this region.

7.0 Conclusion

This report provides a descriptive compilation of stream data collected in Alberta over the past four decades. The data are primarily drawn from historic agricultural and lake management studies.

Current work on stream nutrients is being conducted by various groups. Alberta Agriculture & Forestry's *Alberta Phosphorus Watershed Project* is examining the effectiveness of BMPs. EPCOR is undertaking a similar agricultural assessment project in the Strawberry Creek Watershed.

Various studies on the effects of forest management and forest fires have also been conducted in Alberta, but are not included in this compilation (Smith et al. 2003; Burke et al. 2005; Bladon et al. 2008; Howery 2010; Silins et al. 2014; Bladon et al. 2015).

It is hoped that this report will provide a useful reference point for the next phases of work to support lake eutrophication management in the province.

Appendices

A1 Definitions

Annual Flow-Weighted Mean Concentration (AFWMC): a calculation of the total mass load of a nutrient divided by the total flow volume. This is most often done for a single year, or in colder climates, during the open water season.

Annual Export Coefficient (AEC): a calculation of the total mass load of a nutrient divided by the watershed area for a single year.

Stream year: a single year of measurement for a single stream. Multiple stream years could include multiple years of the same stream and/or multiple streams of the same year.

A2 Land cover details

A3 Stream nutrient data

Table A3-1: Annual flow weighted mean concentrations (AFWMCs) of phosphorus fractions for individual streams. Alternate names for streams in subsequent studies are listed in brackets. Bolded values were derived by NSWA from other reported measurements (annual loads/annual flows). All values are in mg/L.

Table A3-3: Annual flow weighted mean concentrations (AFWMCs) of nitrogen fractions for individual streams. Alternate names for streams in subsequent studies are listed in brackets. Bolded values were derived by NSWA from other reported measurements (annual loads/annual flows). All values are in mg/L.

Table A3-4: Export coefficients of nitrogen fractions for individual streams. Alternate names for streams in subsequent studies are listed in brackets. Bolded values were derived by NSWA from other reported measurements (annual loads/watershed areas). All values are in kg/ha/yr.
